The purpose of this Resilient Design Guide is to provide architects, designers or even homeowners the information necessary to make any set of house plans useful for constructing a more wind resilient structure.

The guide was developed during the course of a two-day charrette that brought together a cross-section of professionals from across the United States. The charrette allowed participants to tap into diverse knowledge and resources provided by professionals, including academics, architects, community outreach organizations, engineers, homebuilders, insurance professionals, manufacturers, product experts, and other building professionals with practical experience before and after high wind disasters, including hurricanes and tornadoes. The group pooled their knowledge and experience to develop an outline for this guide with the goal to provide not only an overview of the “why,” but the “how to” of resilient wind construction. The authors sincerely appreciate the many dedicated professionals that supported this guide.

For more information, contact the Federal Alliance for Safe Homes (FLASH)® at (877)-221-SAFE or visit www.flash.org.
The nonprofit Federal Alliance for Safe Homes (FLASH)® is the country’s leading consumer advocate for strengthening homes and safeguarding families from natural and manmade disasters. The FLASH mission is to promote life safety, property protection and resilience by empowering the families with knowledge and resources for strengthening homes and safeguarding families from disasters of all kinds. Visit www.flash.org.

Architecture for Humanity

Architecture for Humanity is a nonprofit design services firm founded in 1999. By building a more sustainable future through the power of professional design, Architecture for Humanity taps a network of more than 55,000 professionals willing to lend time and expertise to help those who would not otherwise be able to afford their services. They bring design, construction and development services where they are most critically needed. To learn more about Architecture for Humanity and support their work, go to www.architectureforhumanity.org.

The Gulf Coast Community Design Studio (GCCDS) is a professional service and outreach program of Mississippi State University’s College of Architecture, art + design. The GCCDS works through close, pragmatic partnerships with local organizations and communities, regional nonprofits, local governments, universities, developers and other partners across the country to help shape vibrant and resilient Gulf Coast communities. Visit www.gccds.org.

The American Institute of Architects

Founded in 1857, members of the American Institute of Architects consistently work to create more valuable, healthy, secure, and sustainable buildings, neighborhoods, and communities. Through nearly 300 state and local chapters, the AIA advocates for public policies that promote economic vitality and public wellbeing. Members adhere to a code of ethics and conduct to ensure the highest professional standards. The AIA provides members with tools and resources to assist them in their careers and business as well as engaging civic and government leaders, and the public to find solutions to pressing issues facing our communities, institutions, nation and world. Visit www.aia.org.

The Florida Association of the American Institute of Architects

The Florida Association of the American Institute of Architects, headquartered in Tallahassee, represents the interests of more than 3,400 members in Florida. Members adhere to a code of ethics and professional conduct that assures the client, the public, and colleagues of an AIA-member architect’s dedication to the highest standards in professional practice.

The AIA New York Chapter is the oldest and largest chapter of the American Institute of Architects. The Chapter’s members include more than 5,000 practicing architects, allied professionals, students, and public members interested in architecture and design. The AIA New York Chapter is dedicated to three goals: design excellence, public outreach, and professional development.
High Wind Wood Frame Construction

Twenty six percent (approximately 30 million) of U.S. households are in wind zones with an expected wind speed of 110 mph (3-second gust) or greater. Homes in these high wind zones should be designed and built to be strong and weather resistant to improve safety and reduce costly repairs following severe weather. To accomplish these goals, the structure must be designed with an engineered vertical and horizontal load path. That is to say, every component in that path should be engineered to resist a specific wind load. This guide illustrates high wind building design and construction practices, beyond code practices and prescriptive recommendations for this type of added resiliency.

Building Codes

The purpose of this guide is to provide information to designers and homebuilders about high wind construction while outlining options for enhanced resilience with affiliated costs and benefits. Building codes and practices vary throughout the U.S., so users of this guide should become familiar with local building codes and keep in mind that a home can be made more resilient by building beyond the building code. This guide will not detail all building code requirements, but will highlight beyond code and other proven ways to increase resilience.

Wind Zones

Some building codes use different methods to calculate wind forces and the wind zone maps vary accordingly. For example the 3-second gust wind speed of 120 mph used in the International Building Code is equivalent to fastest mile wind speed of 104 mph used in other codes. The map used here is a general guide to wind zones. Detailed maps included with local building codes should be used for determining appropriate design wind speeds.

WIND ZONE MAP

<table>
<thead>
<tr>
<th>Zone 1 / 0–90 mph</th>
<th>Zone 2 / 91–120 mph</th>
<th>Zone 3 / 121–140 mph</th>
<th>Zone 4 / 141–150 mph</th>
</tr>
</thead>
<tbody>
<tr>
<td>Special Zone 1</td>
<td>Special Zone 2</td>
<td>Special Zone 3</td>
<td></td>
</tr>
</tbody>
</table>

Zones are based on values that are nominal design 3-second gust wind speeds in miles per hour (mph) at 33 feet above grade for Exposure Category C. Special zones indicate level of risk for tornado and other straight-line wind events.

Map produced by GCCDS for this guide from FEMA data to show both hurricane wind zones and tornado wind zone activities.
House as a Whole System

Typically, the primary force from wind is lateral (sideways) force. For a wind speed of 150 mph, the wind force is approximately 42 pounds per square foot of wall area. If this load were equated to a roof load, it would compare to the weight of three feet of snow acting horizontally.

Ordinary construction is designed to transfer the vertical loads of a house from the roof to the foundation, and is typically inadequate to resist such high winds. Roof decking, shear walls, clips, straps, and anchor bolts work together to provide lateral support.

In addition to lateral loads, winds produce uplift forces that act dynamically to pull the components of a house apart. The structural system that transfers the force from the walls down to the ground is a set of connected diaphragms, where the roof and the floor decks are stiff horizontal diaphragms that transfer wall loads into vertical shear wall diaphragms. Essential details in roof, floor, and wall diaphragms include sheathing strength and nailing, as well as strong, continuous boundary conditions, such as double top plates, blocking, and rim joists.
Construction Types Used in This Guide

**Ordinary Construction**
Common wood-frame house construction is typically strong enough for wind speeds less than 100 mph. Ordinary wind design construction is illustrated in this guide to give a reference for the typical components of wood frame construction.

**High Wind Construction**
Wind speeds above 100 mph require lateral strength from the roof to the foundation not provided by ordinary wind construction. High wind construction is illustrated in the pages of this guide to help explain what is generally required by various building codes to meet lateral and uplift load requirements for high wind construction standards.

**Resilient Construction**
Houses can be made more resilient by designing for a higher wind load because the safety factor will be increased, making house components more resistant to wind and rain during storms. Increased resilience construction is illustrated in this guide with information regarding costs and expected benefits of making homes more resilient.

These markers are used throughout the guide to indicate whether a building material is considered typical in high wind construction or represents an “increased resilience” construction upgrade.

This icon indicates the cost implication of different components from 1 to 5 with 1 ($) representing baseline construction costs and 5 ($$$$$) representing the most costly.

This icon indicates the construction implication and/or difficulty level from 1 to 5 scale with 1 (()){) representing baseline for ease of construction, need for specialized installation, and ability for skilled labor to complete the work. Five (5) (++){){){){) represents a requirement for highly specialized and skilled labor.
The roof is the primary structural element of the house, transferring the loads that act on the walls facing the wind, into the walls that are parallel to the wind. The main structural components of a roof assembly include:

1. Strong nailing of the roof deck to the framing, especially at the edges
2. Connection of the roof to shear walls with blocking
3. An unbroken double top plate on the shear walls that acts as a structural chord

Roofs are highly exposed to wind and rain and need to be strong as an overall structural system, as well as watertight at any given area on the roof. A resilient roof has two durable layers of protection designed for high winds that include roof covering and underlayment.
Roof Components

COVERINGS
Coverings are the roof’s first line of defense against wind and wind-driven rain. Common residential coverings include asphalt shingles, concrete/clay tiles and metal panels.

UNDERLAYMENT
Underlayment is a secondary layer of roof covering designed to keep moisture from the decking. If a primary covering layer fails, properly installed underlayment will keep water from penetrating the roof and attic. Common underlayment includes 30 lb. felt or tar paper, self-adhesive membranes and membranes that are fully integrated into the decking.

SHEATHING/DECKING
Sheathing/decking is a structural component of a roof typically made of plywood or oriented strand board (OSB) panels. Decking is fastened to the top of the roof framing and makes the framing rigid, so it can transfer loads to the exterior walls.

FRAMING
Framing is the primary structural element of a roof. In this guide, residential framing is limited to wood rafters and wood trusses. Roof framing should be tied to the walls as part of a load path from the roof to the foundation.

HAZARDS

Roofs are the most susceptible component of houses exposed to hurricane force winds. Typically, wind damage to roofs is caused by uplift forces (vertical), suctional and torsional forces (twisting), and horizontal pressures. Wind damage effects vary depending on the roof height, slope, siting and style.

Steep roof systems generally fail at the ridge or along gable ends where wind forces are the highest. Low slope roofs typically fail at roof corners. According to information gathered by FEMA after major storms, the roof component damaged most often in high wind is the roof covering (shingle, tile, etc.), and the second most common damage is sheathing (plywood or OSB decking). Covering failure usually follows use of the incorrect type of fasteners (e.g., nail too small or absence of mechanical attachment on clay tiles, etc). Sheathing damage is more often the result of insufficient attachment (e.g., not enough nails in the nailing pattern). Once the failures occur, they not only expose buildings to water penetration, but also generate windborne debris. When roof systems fail during a hurricane or other high wind events, the rest of the home is weakened and becomes vulnerable to significant, progressive damage.
Ridges, Valleys and Accessories

Roof ridges often experience covering loss in hurricanes or severe windstorms, and vented ridge caps should be properly fastened to ensure adequate resistance. Low profile ridge vents are a good choice as they are less vulnerable in high wind events. Roof valleys are vulnerable in severe weather because they experience significant water flow that can lead to water infiltration. Special care should be taken to follow manufacturers’ specifications to attach all roof elements, including accessories, equipment, solar panels and/or turbine roof vents.

Underlayment and Coverings

Underlayment should be securely fastened to roof decking independently of the roof covering fasteners. Staples are sometimes used to fasten underlayment materials such as felt/tar paper based on the assumption that fasteners used to apply roof shingles on top will secure the underlayment. Unfortunately, in a high wind zone, roof shingles are often lost and this leaves inadequately attached underlayment that cannot prevent water intrusion through deck joints or nail holes. Using a fastener such as a button cap to secure the underlayment will help prevent water intrusion should the coverings fail. Peel-and-stick membrane products also offer superior protection when coverings are lost. Shingles are more wind resistant overall when installed using six versus four nails. Metal and clay tile roof systems should always be attached using manufacturers’ specifications for an increased wind load.
NAIL PATTERNS

Nail patterns describe layout and spacing for a particular attachment of one component to another. Choose the type, size and amount of nails to achieve high wind resilience.

GABLE END WALL

The rake is an overhang at the gable end wall that is particularly vulnerable to wind forces, so it should be adequately and properly attached to the rafters and top of the wall. It is critical to ensure the correct assembly of the edge of the roof framing, decking, underlayment, and coverings to withstand wind forces, as they meet at this location. Gable end walls should be braced back into roof framing and must have a minimum of 7/16" structural sheathing.
**RAFTER AT RIDGE BOARD**

Typical construction practices include cutting out a ridge vent in the roof decking to allow for air to flow freely from inside the attic. This free flow of air causes an unintended weakening of the roof diaphragm at a critical location, because the ridge board serves as a boundary of the roof diaphragm. When the decking is cut away for the vent, the decking is no longer connected between the rafters. Installing a strap or straps will strengthen the connection between rafters while still allowing for roof venting at the ridge.

**RAFTER AT TOP OF WALL**

Rafters attached to the top of a wall in a high wind zone should be fastened to the top plates of the wall with more than just framing nails. Typically, metal connectors, straps, or clips, are specified to hold down the rafter. Eave blocking between the rafters in high winds does more than keep the birds out of the attic; it helps tie the roof diaphragm to the walls and keeps the rafters from rolling due to lateral loads.

**TRUSS AT TOP OF WALL**

When a truss attaches to the top of the wall, it is similar to a rafter in the hold down connection. A metal strap or clip is specified to hold down the truss in the same way a rafter is held down, but the eave blocking detail is somewhat different. Most local building codes do not require full eave blocking when trusses are used for the roof structure; however, 2x4 blocks should be installed to help resist lateral loading.
How a Wall Works in Wind

Three types of wind forces act on walls—wind pressure perpendicular to the wall, lateral loads transferred from the roof to the foundation parallel to the wall, and uplift forces from the roof being lifted from the wall.

The **perpendicular wind force** acts as either positive or negative pressure and is greatest at the corners. The largest wind load is the **parallel lateral load**. This load comes from the roof diaphragm transferred to a shear wall. A shear wall is sheathed with structural panels such as plywood and has critical attachment requirements to the roof and floor framing. Window openings and parts of the wall at corners and between windows that have a length less than 30% of the wall height are not considered part of the shear wall. As a result, windows spaced closely together and windows located closer than 3 feet from corners reduce the shear wall capacity and may require special engineering. The end walls of long, narrow homes are often inadequate shear walls. In such cases, one or multiple interior partitions must be built as shear walls.

High wind zone construction requires use of metal anchors, clips and straps to create a “continuous load path” from the roof to foundation. The well-connected load path allows the structure to resist **uplift forces** because the attachments prevent the roof, wall framing and foundation from separating under uplift and lateral loads.
Wall Components

WALL COVERING

Wall covering, also known as cladding, is the outermost layer of the assembly. Unlike roofs, wall cladding is not sealed from moisture. Instead, cladding protects the water barrier layer beneath from damage. All claddings can provide weather protection, but more durable concrete and masonry materials are preferred for resilient construction by providing better resistance and reduced damage from windborne debris. Common residential wall coverings include brick, fiber cement siding, stucco, vinyl, and wood.

HOUSE WRAP

House wrap, also known as weather resistive barrier (WRB), has the unique ability to stop water from penetrating to the sheathing while still allowing the wall to ventilate.

SHEATHING

Sheathing provides lateral strength and serves as the base for the house wrap and flashing and is part of the wall’s thermal barrier. In high wind zones, sheathing is usually plywood or OSB. Following the specified nail pattern for the sheathing is critical to gain the proper strength.

FRAMING

Framing is the primary structural element of a wall and is most often 2x4 wood studs spaced at 16 inches. Some homes are built using advanced framing which uses 2x6 studs aligned with the roof rafters spaced at 24 inches. Advanced framing offers the advantages of energy and material conservation.

INSULATION

Insulation typically fills space between studs. There are three types of insulation used in homes: batt, blown, or spray foam. All three types can achieve the thermal performance required by code; however, spray foam has structural and sealing advantages that add to resiliency of the home.

Framing
- Top plate to stud strap every other stud and every king stud
- Spray foam insulation in wall cavity
- 2x6 24" O.C. framing with double top plate
- Continuous anchor tie downs (through bolt from top plate to foundation)
- Strap stud to bottom plate strap other stud and every king stud

Sheathing
- 7/16 OSB long length sheathing, attached to floor system, overlap bottom plate by ~12" with WRB fully integrated into sheathing.

Nail Pattern:
4" at edges of sheet, 6" in field, 4" at boundary. Use 8d hot dipped galvanized ring or box shanked nails

House Wrap
- 4" self-adhering polymer modified bitumen flashing tape on all sheathing panel joints

Covering
- Fiber cement siding attached per manufacturers’ specification for high wind zones exposed nailing
HAZARDS

Cladding/Coverings Loss
Siding of any type (wood, vinyl or fiber cement) can blow off a house and become damaging windborne debris. Once siding is blown off, vulnerable house wrap is quickly destroyed exposing the untreated wood sheathing that can suffer damage from wind-driven rain.

Impact from Windborne Debris
Windborne debris impacts are difficult to anticipate; however, a well-constructed assembly with the proper sheathing and cladding attachments will help protect walls from flying debris.

Wind-Driven Water
When cladding is lost, the walls are vulnerable to wind-driven water. A well-attached weather resistive barrier can help to minimize moisture and water infiltration.

Openings & Penetrations
Door and window openings are commonly damaged by wind and wind-driven water. There are vital steps that make doors and windows wind resistant, including following specified installation instructions, using flashing, and deploying locking mechanisms.

HOUSE SHAPE

The shape of a house is material to how it handles lateral loads. For instance, a square house has the same load in every direction because the size of the ends and sides are uniform. Conversely, a long narrow house will experience a much larger load on the long sides than on the short sides. Walls parallel to the lateral load need to be designed and built in a way that anticipates and handles this loading.
Shear walls are structural walls that resist lateral forces acting on a house, and structural panels and framing are the primary components of a shear wall. In high wind zones, exterior walls are typically shear walls. In some cases, interior walls are designed as shear walls if the configuration of the home or size of openings requires more rigidity. Openings create weak points in shear walls and the shear wall strength is discounted for openings. Shear wall design is based on the height and length of a wall, the number and size of openings and the calculated lateral loads based on the specific wind zone location of the home. Shear walls have typical diaphragm nail patterns, e.g., 4" O.C. at edges and 6" O.C. in field. The shear walls must be properly attached to the roof and floor structure in order to properly transfer the loads to the foundation. Interior shear walls should attach to floor/foundation systems much like exterior walls attach to floor/foundation systems.

The method of eave blocking is a significant difference between typical construction and high wind zone construction. Typical eave blocking is commonly referred to as "bird blocking". However, proper blocking between joists performs an essential function as it transfers lateral loads from the roof deck to the shear walls. Eave blocking should be installed during framing before the roof decking is in place. Roof decking should be nailed to the blocking before underlayment is installed.
CLADDING AND COVERING

Brick Veneer
Brick veneer is popular as home cladding because it provides for low maintenance and windborne debris protection; however, it can be vulnerable to wind and wind-driven water in high wind areas. Common brick veneers are secured with masonry ties tied back to the wood frame; however, problems can occur when not enough ties are used, ties are not fastened to the wood frame securely or corrosion sets in. In high wind zones, ties should be spaced closer together and attached through the sheathing to the framing. Also, using proper drainage and drying space will keep the ties and back side of the brick dry and less susceptible to moisture and corrosion.

Vinyl Siding
Vinyl siding is lightweight and susceptible to high wind damage. However, some manufacturers produce vinyl siding systems designed for high winds. Before using vinyl, ask local building suppliers for detailed product information and investigate the past product performance in your area.

Fiber Cement Siding
Fiber cement siding is popular as home cladding because it provides for low maintenance and windborne debris protection. Manufacturers provide for high wind by providing details for enhanced attachment with higher grade fasteners and closer placement. Roofing nails with larger heads are often specified in place of specialized “siding” nails. And, like masonry ties, fasteners should be attached to the wood frame behind the sheathing.
**DESIGN PRESSURE (DP) RATINGS**

Design Pressure (DP) ratings on windows should not be confused with impact ratings as they are based solely on the wind load the windows are designed to withstand. DP ratings and requirements vary by the home’s wind zone location as well as window location in the wall. For example, DP rating requirements in the middle of the wall where pressure is lower than those near the edges where pressure is greater. Refer to your local building authority to identify appropriate DP Ratings.

**IMPACT WINDOWS**

Impact-resistant windows are tested and rated with large and small missile impacts. Windows are required to remain intact after impact; however, glass breakage is allowed as along as the glass does not fall out of the window.

**Large Missile**
6' nine lb. 2x4 fired at 50FT/S

**Small Missile**
30 pieces of roof gravel fired at 80FT/S

When local building codes in high wind zones require impact-resistant windows, they often allow for product substitutions due to cost considerations.

**SHUTTERS, PANELS, ETC.**

Many products are available that can work in place of, or supplement the strength of, impact-resistant windows. Shutters decrease the chance of breaking glass.
**INSTALLATION**

Window installation is critical to window performance in the wall, so using the correct DP rating and impact resistance attributes will not matter if the installation is not correct. All window manufacturers specify the correct means of installation, and high wind resilience can be achieved by following the manufacturers’ installation guidelines for increased wind load.

**SELF-ADHERED FLASHING**

Self-adhered flashing, commonly called “window tape,” is vital to securely seal window openings. Tape should be installed after the window is secured in place from the bottom sections first and up to the top. Each section above should overlap the section below to create an effective drainage path.

**Supplemental Information – Doors**

Doors are weak parts of the wall and must be detailed correctly to keep wind and wind-driven rain out of the home. During a 130 mph wind (Category 4 hurricane), a typical 3’ wide door will experience approximately 580 pounds of pressure. As with windows, the glass sections in doors are the most vulnerable. Door glass panels have their own DP and impact ratings although they are similar to windows ratings. Common areas where doors fail are outlined on the following pages.

DOOR TO JAMB AND FRAME

Latch
A common weak point is the latch and lock because high winds can concentrate large forces on that single point. Many new door models have three and five point latching as opposed to the traditional single point at the latch and handle, which creates a stronger door to door frame connection.

Hinges
The hinge side of the door is also a major concern. Door hinges need specific attachments to the door frame and door to ensure proper connection.

Jamb and Frame to Wall
If the door jamb and frame are not properly attached to the structure, the door system will fail. All door manufacturers provide detailed specifications on how to attach the system to the structure of the home.

FRENCH DOBLE DOORS

Double doors often fail in high winds because they are weak where they come together, especially if they swing inward. Some units use a center post to create a stronger latch point; however, the post somewhat defeats the purpose of a double door configuration. More manufacturers are offering out-swinging double door models, and they are sometimes required by local building codes.
**GARAGE DOORS**

Like doors and windows, garage doors are a weak part of the wall, especially because most garages are designed to make the door opening as wide as possible. This wide opening requires a strong door frame that is commonly referred to as a “moment frame”. The wind load on a garage door is substantial. A typical 10’ x 10’, single car garage door is subject to more than 6000 lbs. of pressure in 130 mph winds. Garage doors must be rated for pressures associated with the site design, wind speed, and exposure category. Garage doors are commonly made of thin sheet metal, fiberglass or similar materials so that they are lightweight for efficient lifting. As a result, they are vulnerable to damage by wind forces and windborne debris. Glass panels in garage doors are not recommended because they introduce additional weakness and glass panel, wind-rated garage doors are expensive options for typical residential construction. Roll up doors are often connected at only a few critical points. The concentrated loads on the edges must be accounted for when attaching garage doors. Anchoring into the wall is vital just as it is for windows and doors. Thresholds poured into the garage slab or installed onto the garage floor help keep out wind-driven water.

**WIND-DRIVEN WATER**

**Seal**

Doors should be properly flashed and sealed for both wind and wind-driven water. All four sides of the door should seal tight to the frame, and all four sides of the frame should be sealed tight to the structure. A combination of flashing and sealers such as caulking, foam and silicone should be used.

**Thresholds**

The threshold is the bottom of the door frame and provides transition from outside to inside. Thresholds can be particularly vulnerable to wind-driven water. Sealing the bottom of the threshold to the door frame is important and is often overlooked at the time of installation.
**TOP OF WALL**

The top chord of the wall is made of two 2x4 framing members. The top plate is doubled so that the strength of the chord is not lost at splices. Wind forces on the face of the wall pull the top plate from the stud. Hold down straps keep the top plate from overturning when an uplift force is acting on the roof structure. A hold down strap that wraps over the top and connects to both sides of the stud is recommended.

**WALL AT RAISED FLOOR**

The wall at a raised floor should use longer sheathing, known as a combined use wood structural panel, to overlap the bottom plate and attach to the floor framing members. This creates a connection from the top of the wall to the bottom of the floor framing. Additional straps can be used to strengthen the connection of the wall to the floor framing.

**WALL AT SLAB-ON-GRADE**

Just like the double top plate, the bottom plate (or sole plate) needs to be attached to the wall studs so they act as one structural element. There are metal straps and clips that help with this. The other major connection point is the bottom plate to the slab or grade beam. This connection is made with an anchor bolt that is embedded in the concrete when it is poured. Epoxy-set anchors can be used as retrofits if the concrete slab has already been poured or if there is a missing or misaligned anchor.
The primary structural role of the floor and foundation is to transfer the lateral loads into the ground. The accumulated forces from high winds are significant at foundations and the effects of such forces are increased in homes that are built on tall piers, a common practice in coastal flood zones. Elevated piers, which are built in the ground, or piles, which are driven into the ground, are generally eight or more feet deep depending on the soil capacity and should be designed by an engineer.

In a two-story home, the second floor deck is a stiff horizontal diaphragm that transfers the loads on the walls facing the wind to the wall parallel to the wind. Whether the foundation is a slab-on-grade or a framed floor, the attachment of the walls to the floor is one of the most important structural details as this anchor condition transfers the lateral and uplift wind loads from the wall to the floor.
Foundation Components

SUBFLOOR
The subfloor is a horizontal diaphragm for either a ground floor or upper floor. As with the roof and wall sheathing, the strength of the plywood or OSB and the strength of the attachments are important. Floor decking is often glued and fastened to the floor framing.

FLOOR FRAMING
Floor framing is typically 2 x 10, 2 x 12 or engineered lumber. The size of the framing is determined by the spans and floor loads.

INSULATION
Insulation in raised floors should be tight to the underside of the decking unless another “air barrier” is created at a different location, e.g., the bottom of the framing members. Rigid insulation and spray foam insulation are recommended in high wind zones as these two types of applications deliver energy-efficiency, water resistance, and structural strength as opposed to batt and blown in insulation that only provide energy-efficiency.

SILL PLATES AND ANCHORS
Sill plates are anchored to the foundation with anchor bolts cast into the foundation. The spacing and size of the anchor bolts are determined by the lateral loads.

FOUNDATIONS
Houses have various foundation systems. A slab-on-grade is the floor and the foundation when it is used. If the floor is elevated or has a crawl space, the foundation consists of a vertical member and a footing. The vertical member is either a stem wall or a pier, which is typically reinforced concrete block or cast-in-place concrete. The footing type depends upon the soil strength and whether the home is elevated. Typical footings are either spread footings under each pier, continuous spread footings for a stem wall or combined piers, or deep foundations such as concrete piers or driven piles.

</table>
Ordinary construction

Typical components of wood frame construction

- 3/4" tongue and groove sub floor (glued and nailed to framing)
- 2x floor joists (depth is span dependent)
- 2x double rim joist/beam
- Sill plate with anchor bolts
- Concrete masonry or cast-in-place unit piers filled with continuous rebar tied into foundation per local code
- 24" x 24" spread footings with rebar, sized and designed by engineer based on soil conditions.

$ Raised Floor

Flooring

- Anchor bolts from slab into bottom plate 1/2" "J" bolts 48" O.C. + 1 "J" bolt within 12" of corners
- Reinforced slab and grade beam sized and designed by engineer

$ Slab-on-grade
High Wind Construction

Generally required by various high wind building codes

- Flooring
  - Anchor bolts from slab into bottom plate 5/8" "J" bolts 18" O.C. + 1 "J" bolt within 12" of corners
  - Foam gasket between foundation and bottom plate
  - Reinforced slab and grade beam sized and designed by engineer.

- Slab-on-grade

- $  Slab-on-grade

- $  Raised Floor

- 3/4" tongue and groove sub floor (glued and nailed to framing)
- 2x floor joists (depth is span dependent)
- 2x double rim joist and beam
- Hold down bolted through bottom plate and bolted into foundation.
- Sill plate with anchor bolts
- Concrete masonry or cast-in-place unit piers or continuous wall filled with continuous rebar tied into foundation per local code sized and designed by engineer.
- Continuous footings per design professional. A continuous footing is a stiffer foundation and makes the house more rigid and stronger in high winds.
- Batt insulation covered with vapor barrier attached with button caps

[Diagram of High Wind Construction with annotations]
**Resilient Construction**

Reduces the damaging effects of a storm

- 1-1/8” tongue and groove sub floor attached with screws and adhesive
- Engineered floor joists (stronger, straighter, and more stable than solid wood)
- 2x double bottom plate
- Hold down bolted through bottom plate and bolted into foundation.
- Sill plate with anchor bolts
- Concrete masonry or cast-in-place unit piers or continuous wall filled with continuous rebar tied into foundation per local code, sized and designed by engineer.
- Continuous footings per design professional. A continuous footing is a stiffer foundation and makes the house more rigid and strong in high winds.
- Fiber cement panels with batten strip

- **Raised Floor**

---

### Slab-on-grade

- **$**
- **Slab-on-grade**

- Anchor bolts from slab into bottom plate 5/8” “J” bolts 16” O.C. + 1 “J” bolt within 12” of corners
- Foam gasket between foundation and bottom plate
- Reinforced slab and grade beam, sized and designed by engineer.
HAZARDS

Floors and foundations are generally more susceptible to flood damage than from wind damage during storms. Many high wind locations are also coastal flood zones, and those zones require elevated homes. Unfortunately, elevated foundations significantly increase the wind hazard of a home because the lateral loads acting on the home cause a substantial overturn when forces exert pressure on piers. Added foundation height increases the load exponentially. Thus, the connection from the wall to the foundation is critical to resist overturning.

FLOORING

Subfloors for raised floors are typically plywood and OSB panels. They are typically between 3/4" and 1-1/8" thick and attached with a polyurethane construction sub-floor adhesive.

NAILING PATTERNS

Recommended floor sheathing nail patterns are 4" at edges of exterior walls, 6" at panel edges and 8" in the field.
SLAB-ON-GRADE FOUNDATIONS

Slab-on-grade floors and foundations are poured at the same time and form a monolithic structure. Walls are anchored into the foundation at the edges and thickened slabs or grade beams can be installed where extra structure is needed.

In high wind zones, anchor bolts are typically required at 18” O.C.; however, since 18” spacing is out of sync with typical 16” spaced studs, 16” anchor bolt spacing is recommended.

INTERIOR SHEAR WALLS

Interior shear walls should be fastened to the floor or foundation. If on a slab, the interior shear walls should have anchor bolts in the slab similar to the exterior walls. In addition, the concrete slab may be thickened to provide the extra structure as needed where the interior shear walls are anchored. If on a raised foundation, hold down straps help to connect the wall to the floor and roof framing.
Resilient Landscape

HAZARDS

Falling trees account for most of the major wind damage to houses in hurricanes. In storms like Hurricane Katrina with wind speed more than 120 mph, approximately 20% of the urban trees toppled. In Hurricane Andrew, 38% of the affected trees toppled. Beyond wind intensity, other storm factors influencing tree damage include:

- **Amount and duration of rain**
- **Tree species, age and condition**
- **Soil characteristics**

Even though it is not possible to build a home strong enough to withstand the impact of a large tree, it is possible to plan and maintain landscapes that reduce the risk of trees falling on a home. Certain species are more vulnerable to wind damage such as various southern pine, pecan, red oak and water oak. Moreover, as every tree has an inherent life span, older trees of species with shorter life spans are most susceptible to storm damage.

LANDSCAPING

Trees benefit homeowners by beautifying the yard, attracting songbirds, providing protection from wind and noise and by shading the yard and home. However, falling trees and limbs are often the source of storm damage to homes. Three factors regarding trees should be considered: condition, location and species. Limbs on healthy trees that hang over the roof should be trimmed back and any unhealthy or unstable trees should be removed.

In addition to trees, a resilient landscape takes into account manmade elements that might cause damage from wind such as fences, flag poles, lawn furniture and light fixtures. These elements, as well as building components such as gutters, downspouts and exterior air conditioning equipment, should be secured.

AUXILIARY STRUCTURES  Gazebos, Pavilions, Pergolas

Outdoor covered structures are usually supported by horizontal beam members sitting on vertical columns which must be correctly connected to the foundation to prevent uplift and wind damage.
The most common result of wind storms is loss of electrical power due to trees and limbs falling on power lines. Ideally, electrical services are run underground as this reduces risk of power outages; and communities benefit from these types of efforts to invest in more resilient power infrastructure. For the individual homeowner, loss of electrical power is not only inconvenient, but the lack of air conditioning allows mold growth inside the home. A resilient home is prepared for loss of power with good natural ventilation and a standby generator to provide power for a minimal amount of air conditioning and interior finishes that don’t support mold growth.

Loss of electrical power in a neighborhood can also affect the water and sewage system. Sewage check valves and back flow preventers can be used on homes to guard against contamination from systems that might not operate normally after a disaster.

Placement Details

Install the generator set:
- Outdoors
- Near the incoming gas service
- Near the main electrical panel(s)
- On a flat, level mounting area

**IMPORTANT PLACEMENT GUIDELINES**

- The recommended distance from a structure is dependent on state and local codes.
- Locate the generator set so that the hot exhaust does not blow on plants or other combustible materials. No plants, shrubs, or other combustible materials are allowed within 1.2 m (4 ft.) of the exhaust end of the generator set.
- Do not install the generator set where exhaust gas could accumulate and seep inside or be drawn into a potentially occupied building. Furnace and other similar intakes must be at least 3 m (10 ft.) from the exhaust end of the generator set.
- Do not locate the generator set near patios, decks, play areas, or animal shelters.
- Do not install the composite mounting pad directly on grass, wood, or other combustible materials. Clear all combustible materials, including plants and shrubs, building materials, and lawn furniture, from an area at least 1.2 m (4 ft.) beyond the exhaust end of the generator.
- In flood hazard areas, locate the generator and its control systems above the highest expected flood level.
- In high wind areas, the generator should be securely mounted to a concrete pad according to the mounting instructions in the installation manual.
Roof

Spray Foam
When applied to the underside of the roof deck, closed-cell spray polyurethane foam insulation has various characteristics to provide a sealed roof deck and secondary water barrier performance.

Properly applied spray foam can be considered as an impermeable insulation. Controlled air permeability helps to prevent and control bulk water entry which create a sealed roof deck. Spray foam can also be considered a water/secondary resistive barrier and provides support against wind uplift and racking.

For resilient construction consider applying a 3” minimum full insulating layer between roof rafters/trusses.

Thank You

We would like to thank and recognize the following individuals and their respective organizations for their donation of expertise, time and commitment to the creation and publication of the Resilient Design Guide. Their generosity and passion for making America a more disaster-resilient nation are evident in their unconditional support for this project.
